A low-energy non-unitary leptonic mixing matrix is a generic effect of some theories of new physics accounting for neutrino masses. We show how the extra CP-phases of a general non-unitary matrix allow for sizeable CP-asymmetries in the $\nu_\mu \rightarrow \nu_\tau$ channel. This CP-asymmetry turns out to be an excellent probe of such new physics.

1 Introduction

Non-zero neutrino masses constitute one of the main pieces of evidence for physics beyond the Standard Model of particle physics (SM). In the complete theory accounting for them and encompassing the SM the complete mixing matrices should be unitary, as mandated by probability conservation. However, the effective 3×3 submatrices describing the mixing of the light fermionic fields need not to be unitary, since these known fields in the theory may mix with other degrees of freedom. We will assume that the full theory is indeed unitary, whereas, low-energy non-unitarity may result from BSM physics contributing to neutrino propagation, when the physical measurements are described solely in terms of SM fields¹. Specifically, the tree-level exchange of heavy fermions (scalars) will (not) induce low-energy non-unitary contributions through dimension six effective operators².

In Ref.¹ the so-called MUV (minimal unitarity violation) was developed and the *absolute* values of the elements of the matrix N were determined. However, no information on the phases of the mixing matrix is available, neither on the standard phases nor on the new non-unitary ones, as present oscillation data correspond mainly to disappearance experiments. Here we will explore the future sensitivity to the new CP-odd phases of the leptonic mixing matrix associated to non-unitarity. In particular, it will be shown that CP-asymmetries in the $\nu_\mu \rightarrow \nu_\tau$ channel are an excellent probe of such new physics. Notice that CP-odd effects in that channel are negligible in the standard unitary case, in which the golden channel for CP-violation is $\nu_e \rightarrow \nu_\mu$.

2 Formalism

We start from the parametrization of the general non-unitary matrix N , which relates flavor and mass fields, as the product of a hermitian and a unitary matrix, defined by

$$\nu_\alpha = N_{\alpha i} \nu_i \equiv [(1 + \eta)U]_{\alpha i} \nu_i, \quad (1)$$

with $\eta^\dagger = \eta$. Since $NN^\dagger = (1 + \eta)^2 \approx 1 + 2\eta$, the bounds derived in Ref.¹ for the modulus of the elements of $NN^\dagger$ can also be translated into constraints on the elements of η . It follows that

$$|\eta| = \begin{pmatrix} < 5.5 \cdot 10^{-3} & < 3.5 \cdot 10^{-5} & < 8.0 \cdot 10^{-3} \\ < 3.5 \cdot 10^{-5} & < 5.0 \cdot 10^{-3} & < 5.1 \cdot 10^{-3} \\ < 8.0 \cdot 10^{-3} & < 5.1 \cdot 10^{-3} & < 5.0 \cdot 10^{-3} \end{pmatrix}, \quad (2)$$

at the 90% confidence level. The bounds have been updated with the latest experimental bound on $\tau \rightarrow \mu\gamma$ ³. Eq. (2) shows that the matrix N is constrained to be unitary at the per cent level accuracy or better. Therefore, the unitary matrix U in Eq. (1) can be identified with the usual unitary mixing matrix $U = U_{PMNS}$, within the same accuracy. The flavor eigenstates can then be conveniently expressed as^a

$$|\nu_\alpha\rangle = \frac{(1 + \eta^*)_{\alpha\beta} U_{\beta i}^*}{[1 + 2\eta_{\alpha\alpha} + (\eta^2)_{\alpha\alpha}]^{1/2}} |\nu_i\rangle \equiv \frac{(1 + \eta^*)_{\alpha\beta}}{[1 + 2\eta_{\alpha\alpha} + (\eta^2)_{\alpha\alpha}]^{1/2}} |\nu_\beta^{SM}\rangle. \quad (3)$$

So the neutrino oscillation amplitude, neglecting terms quadratic in η , is given simply by

$$\langle \nu_\beta | \nu_\alpha(L) \rangle = A_{\alpha\beta}^{SM}(L) (1 - \eta_{\alpha\alpha} - \eta_{\beta\beta}) + \sum_\gamma (\eta_{\alpha\gamma}^* A_{\gamma\beta}^{SM}(L) + \eta_{\beta\gamma} A_{\alpha\gamma}^{SM}(L)), \quad (4)$$

with

$$A_{\alpha\beta}^{SM}(L) \equiv \langle \nu_\beta^{SM} | \nu_\alpha^{SM}(L) \rangle \quad (5)$$

being the usual oscillation amplitude of the unitary analysis.

In order to study the possible new CP-violation signals arising from the new phases in η , one has to consider appearance channels, $\alpha \neq \beta$. The best sensitivities to such phases will be achieved in a regime where the first term in Eq. (4) is suppressed. This is possible at short enough baselines, where the standard appearance amplitudes are very small while $A_{\alpha\alpha}^{SM}(L) \simeq 1$. In that case the total amplitude is well approached by

$$\langle \nu_\beta | \nu_\alpha(L) \rangle = A_{\alpha\beta}^{SM}(L) + 2\eta_{\alpha\beta}^* + \mathcal{O}(\eta A), \quad (6)$$

where $\mathcal{O}(\eta A)$ only includes appearance amplitudes and η components with flavor indices other than $\alpha\beta$. Then, at short enough baselines, each oscillation probability in a given flavor channel, $P_{\alpha\beta}$, is mostly sensitive to the corresponding $\eta_{\alpha\beta}$. The rest of the elements of the η matrix can be safely disregarded in the analysis below, without implying to assume zero values for them. That is, their effect is subdominant, a fact that has been numerically checked for the main contributions.

For instance, within the above-described approximation, the oscillation probability for two families would read:

$$P_{\alpha\beta} = \sin^2(2\theta) \sin^2\left(\frac{\Delta L}{2}\right) - 4|\eta_{\alpha\beta}| \sin \delta_{\alpha\beta} \sin(2\theta) \sin(\Delta L) + 4|\eta_{\alpha\beta}|^2, \quad (7)$$

where $\Delta = \Delta m^2/2E$ and $\eta_{\alpha\beta} = |\eta_{\alpha\beta}| e^{-i\delta_{\alpha\beta}}$. The first term in the above equation is the standard oscillation probability. The third term is associated to the zero-distance effect stemming from the non-orthogonality of the flavor eigenstates¹. Finally, the second term is the CP-violating interference between the other two which we are interested in. Notice that, even in two families, there is CP-violation due to the non-unitarity.

^aThe handy superscript SM is an abuse of language, to describe the flavor eigenstates of the standard unitary analysis.

Figure 1: *Left: 3 σ contours for two input values of $|\eta_{\mu\tau}|$ and $\delta_{\mu\tau}$ represented by the stars. Right: the solid line represents the 3 σ sensitivity to $|\eta_{\mu\tau}|$ as a function of $\delta_{\mu\tau}$, the dotted line the 3 σ sensitivity to $\delta_{\mu\tau}$ and the dotted-dashed line represents the present bound from $\tau \rightarrow \mu\gamma$.*

3 Sensitivity to the new CP-odd phases: the $\nu_\mu \rightarrow \nu_\tau$ channel

This channel is the best option to study the CP-violation coming from non-unitarity. This is because present constraints on $\eta_{e\mu}$ are too strong to allow a signal in the $\nu_e \rightarrow \nu_\mu$ one (see Eq. (2)), and $\nu_e \rightarrow \nu_\tau$ has extra suppressions by small standard parameters such as $\sin\theta_{13}$ or Δ_{12} ⁴. In the numerical computation of $P_{\mu\tau}$, the only approximation performed is to neglect all η elements but $\eta_{\mu\tau}$. They should be indeed subdominant (see Eq. (6)). This approximation has been checked numerically.

Eq. (7) suggests us that the best sensitivities to CP-violation will be achieved at short baselines and high energies, where the standard term is suppressed by $\sin^2(\frac{\Delta L}{2})$. Therefore, we will study a Neutrino Factory beam⁵ resulting from the decay of 50 GeV muons, to be detected at a 130 Km baseline, which matches for example the CERN-Frejus distance. For this set-up, $\sin(\frac{\Delta_{31}L}{2}) \simeq 1.7 \cdot 10^{-2}$ and $\sin(\frac{\Delta_{21}L}{2}) \simeq 6 \cdot 10^{-4}$, where $\Delta_{jk} \equiv (m_j^2 - m_k^2)/2E$. Then, if the $\eta_{\mu\tau}$ value is close to their experimental limit in Eq. (2), all terms in the oscillation probability given in Eq. (7) can be of similar order for the channel $\nu_\mu \rightarrow \nu_\tau$. On the experimental side, we will assume $2 \cdot 10^{20}$ useful decays per year and five years running with each polarity, consider a 5 Kt Opera-like detector and, finally, sensitivities and backgrounds a factor 5 larger⁴ than those used for the $\nu_e \rightarrow \nu_\tau$ channel in Ref.⁶.

Since this channel is not suppressed by small standard parameters such as $\sin\theta_{13}$ or Δ_{12} , the two family approximation in Eq. (7), with $\theta = \theta_{23}$ and $\Delta = \Delta_{31}$, is very accurate to understand the results^b. This equation indicates that the CP-odd interference term is only suppressed linearly in $|\eta_{\mu\tau}|$. This can indeed be observed in the result of the complete numerical computation, Fig. 1, which shows the sensitivities to $|\eta_{\mu\tau}|$ and $\delta_{\mu\tau}$ obtained. The left panel represents two fits to two different input values of $|\eta_{\mu\tau}|$ and $\delta_{\mu\tau}$ (depicted by stars). The dashed lines correspond to fits done assuming the *wrong* hierarchy, that is the opposite sign for Δ_{31} to that with which the number of events were generated. As expected from Eq. (7), a change of sign for the mass difference can be traded by a change of sign for $\delta_{\mu\tau}$. Nevertheless, this does not spoil the potential for the discovery of CP violation, since a non-trivial value for $|\delta_{\mu\tau}|$ is enough

^bThe complete expanded expression for $P_{\mu\tau}$ can be found in Ref⁴.

to indicate CP violation. Furthermore, the sinusoidal dependence implies as well a degeneracy between $\delta_{\mu\tau} \rightarrow 180^\circ - \delta_{\mu\tau}$, as reflected in the figure.

The right panel in Fig. 1 depicts the 3σ sensitivities to $|\eta_{\mu\tau}|$ (solid line) and $\delta_{\mu\tau}$ (dotted line), while the present bound from $\tau \rightarrow \mu\gamma$ is also shown (dashed line). The poorest sensitivity to $|\eta_{\mu\tau}|$, around 10^{-3} , is found in the vicinity of $\delta_{\mu\tau} = 0$ and $\delta_{\mu\tau} = 180^\circ$, where the CP-odd interference term vanishes and the bound is placed through the subleading $|\eta_{\mu\tau}|^2$ term. The latter is also present at zero distance and its effects were already considered in Ref. ¹, obtaining a bound of similar magnitude. The sensitivity to $|\eta_{\mu\tau}|$ peaks around $|\eta_{\mu\tau}| \simeq 4 \cdot 10^{-4}$ for $\delta_{\mu\tau} \simeq \pm 90^\circ$, where $\sin \delta_{\mu\tau}$ is maximum. That is, for non-trivial values of $\delta_{\mu\tau}$ not only CP-violation could be discovered, but values of $|\eta_{\mu\tau}|$ an order of magnitude smaller could be probed.

4 Conclusions

The flavour mixing matrix present in leptonic weak currents may be generically non-unitary, as a result of new physics responsible for neutrino masses. Even if the effects are expected to be extremely tiny in the simplest models of neutrino masses, it is important to analyze the low-energy data without assuming a unitary leptonic mixing matrix, since it is a generic window of new physics.

A non-unitary matrix has more moduli and phases than a unitary one. The last ones may lead to new signals of CP-violation. In particular, we have shown that an asymmetry between the strength of $\nu_\mu \rightarrow \nu_\tau$ oscillations versus that for $\bar{\nu}_\mu \rightarrow \bar{\nu}_\tau$ results to be a beautiful and excellent probe of new physics, considering short-baselines (~ 100 km.) and a Neutrino Factory beam of energy $\mathcal{O}(20\text{GeV})$. Non-trivial values of the new phases can also allow to probe the absolute value of the moduli down to 10^{-4} , an improvement of an order of magnitude over previous analyzes of future facilities.
